0. Introduction

Let Φ be a finite crystallographic root system with Weyl group W. In [**BC2**], Brenti and Carnevale consider the sign-twisted Poincaré series

$$F(\Phi; q) := \sum_{w \in W} \operatorname{sgn}(w) q^{\ell_1(w)},$$

where $\ell_1(w)$ denotes the number of "odd inversions" of w; i.e., the number of positive roots of odd height mapped to negative roots by w. In particular, they give an explicit product formula for the above series in all cases except E_8. For the root systems B_n and C_n, they also have multivariate refinements that keep track of more detailed information about the odd inversions, and in earlier work for types A and B [**BC1**], they consider variations that include restricting the series to the distinguished coset representatives for any parabolic quotient W/W_J.

Among their motivations, we should mention work of Klopsch and Voll [**KV**]. In the course of enumerating flags of subspaces over a finite field that are non-degenerate with respect to various classes of bilinear forms, they conjectured a formula (proved in [**BC1**]) that amounted to an explicit evaluation of the above series restricted to any parabolic quotient in type A. A similar explicit evaluation for parabolic quotients in type B arose conjecturally in the work of Stasinski and Voll [**SV2**] on the zeta functions for certain group schemes. (This conjecture was proved independently in [**BC1**] and [**L**].)

The main goal of the present article is to provide further insights into these sign-twisted series, with an emphasis on unified, classification-free results. For example, it seems natural from the perspective of general root systems to exploit the fact that the reflections corresponding to the even roots permute the odd roots. Although this diverges somewhat from the point of view taken in [**BC2**] (see Remark 6.2 below), it leads to multivariate refinements that share the common feature that odd roots in the same "even orbit" are given the same weight. Thus the multivariate series we consider here involve 2 variables for A_n, B_n, F_4 and G_2, and 4 variables for C_n.

Our main results are as follows:

1. A combinatorial quotient theorem proving that for every parabolic subsystem Φ_J, the corresponding series $F(\Phi_J; q)$ is a divisor of $F(\Phi; q)$ (see Theorem 5.1 and its corollaries). This makes it clear *a priori* (i.e., without use of the classification of finite root systems) that the series $F(\Phi; q)$ necessarily has many irreducible factors.

2. An explicit product formula for the multivariate series for each irreducible root system (Theorem 6.1). The proof is by induction with respect to rank, using Theorem 5.1. Each inductive step requires the evaluation of a sign-twisted sum over a small number of right coset representatives. In the classical cases, there are only 2 or 4 terms in each sum.

3. A general result that identifies, in a classification-free way, sufficient conditions for the multivariate series for a parabolic quotient W/W_J to be the ratio of the corresponding series for W and W_J (Theorem 7.1). Conjecturally, the conditions are also necessary.

4. A uniform presentation of the univariate product formula, revealing that

$$F(\Phi; q) = (1 - q^{a_1}) \cdots (1 - q^{a_k}),$$

where $a_1, \ldots, a_k$ are the degrees of the free generators of the polynomial invariants of a certain reflection group canonically associated to Φ (Theorem 8.5). Although our only proof of this formula is case-by-case, it does suggest a possible framework for a classification-free approach to the factorization of $F(\Phi; q)$.

1. Preliminaries

Throughout, V shall denote a real Euclidean space with inner product $\langle \cdot, \cdot \rangle$ and $\Phi \subset V$ a finite crystallographic root system with co-root system $\Phi^\vee = \{\beta^\vee : \beta \in \Phi\}$, positive roots Φ^+, and Weyl group $W = W(\Phi)$. We use a common index set I for the simple roots $\{\alpha_i : i \in I\} \subset \Phi$ and simple reflections $\{s_i : i \in I\} \subset W$. We will embed $\Phi^\vee$ in V by taking $\beta^\vee = 2\beta/\langle \beta, \beta \rangle$.

If L is a sublattice of the root lattice $\mathbb{Z}\Phi$, it is easy to show that $\Phi \cap L$ is again a root system in V, possibly of lower rank. The main lattice of interest here is

$$L_0 := \Big\{ \sum a_i \alpha_i : a_i \in \mathbb{Z}, \ \sum a_i \text{ even} \Big\}.$$

This has index 2 in $\mathbb{Z}\Phi$, and thus partitions Φ into "even" and "odd" roots; i.e.,

$$\Phi = \Phi_0 \cup \Phi_1,$$

where $\Phi_0 = \Phi \cap L_0$ is the root subsystem consisting of all roots of even height, and Φ_1 is the set of roots with odd height. Note that the even Weyl group $W(\Phi_0)$ necessarily permutes Φ_0 and Φ_1.

Recall that the length function on W counts inversions; i.e., $\ell(w) = |\Phi(w)|$, where

$$\Phi(w) = \{\beta \in \Phi^+ : -w\beta \in \Phi^+\}.$$

We may thus refine length by separating the contributions of even and odd roots; i.e.,

$$\ell(w) = \ell_0(w) + \ell_1(w),$$

where $\ell_i(w) := |\Phi_i(w)|$ and $\Phi_i(w) := \Phi_i \cap \Phi(w)$.

As discussed in the introduction, our central object of interest is the series

$$F(\Phi; q) := \sum_{w \in W} \text{sgn}(w) q^{\ell_1(w)}. \tag{1.1}$$

Note that since every nontrivial $w \in W$ inverts at least one simple (and therefore odd) root, it follows that $F(\Phi; q)$ has constant term 1. Likewise, since there is a unique element

that inverts all of the simple roots (the longest element), it is therefore also the unique element that inverts all of the odd roots. Thus the degree of $F(\Phi; q)$ is the number of odd positive roots.

It would be reasonable to consider a generalization of (1.1) in which the pair (Φ_0, Φ_1) is replaced with $(\Phi', \Phi \setminus \Phi')$ for *any* root subsystem $\Phi' \subset \Phi$. However, it should be noted that the corresponding series will vanish unless Φ' contains none of the simple roots of Φ. Indeed, the simple reflection s_i has only one inversion—the simple root α_i. If this simple root belongs to Φ', then s_i must necessarily permute $\Phi^+ \setminus \Phi'$. Thus multiplication by s_i would change the sign while preserving the number of inversions not in Φ'. That is, the contributions from pairs (w, ws_i) would cancel out.

We remark that each equal rank real form of a complex semisimple Lie group with root system Φ induces a parity function on Φ (more precisely, a homomorphism $\mathbb{Z}\Phi \to \mathbb{Z}/2\mathbb{Z}$) defined up to the action of W. The even roots in this setting correspond to the roots of the maximal compact subgroup. Thus the parity function we are concerned with here is associated to the quasisplit equal rank real form; i.e., the case where there is a positive system in which all simple roots have odd parity. (See for example [**Kn**], especially Chapter VI and the discussion surrounding (6.99).)

For each $J \subseteq I$, we let Φ_J denote the parabolic subsystem of Φ generated by $\{\alpha_j : j \in J\}$, and $W_J = W(\Phi_J) = \langle s_j : j \in J \rangle$ the associated Weyl group. It is well known that

$$W^J := \{w \in W : \ell(ws_j) > \ell(w) \text{ for all } j \in J\},$$
$$^J W := \{w \in W : \ell(s_j w) > \ell(w) \text{ for all } j \in J\},$$

are minimum-length representatives for the left and right cosets of W_J in W, respectively. Moreover, one has $\ell(xy) = \ell(x) + \ell(y)$ for all $x \in W^J$, $y \in W_J$ and all $x \in W_J$, $y \in {}^J W$.

The following key feature of inversion sets will be used repeatedly.

LEMMA 1.1. *For all $x, y \in W$ such that $\ell(xy) = \ell(x) + \ell(y)$, we have*

$$\Phi(xy) = \Phi(y) \,\dot\cup\, y^{-1}\Phi(x) \quad \textit{(disjoint union)}.$$

Proof. It is clear that if $\beta \in \Phi^+$ is an inversion of xy, then either $y\beta < 0$, or $y\beta > 0$ and $xy\beta < 0$; i.e., $\beta \in \Phi(y)$ or $y\beta \in \Phi(x)$. Thus $\Phi(xy) \subseteq \Phi(y) \cup y^{-1}\Phi(x)$. If this union failed to be disjoint, or the inclusion was proper, then we would have

$$\ell(xy) = |\Phi(xy)| < |\Phi(x)| + |\Phi(y)| = \ell(x) + \ell(y),$$

a contradiction. $\quad\square$

2. Orbits of odd roots

Recall that the even Weyl group $W(\Phi_0)$ permutes the odd roots; the structure of these orbits will play a key role in what follows. The W-orbit structure is well-known: two roots (whether or not they are odd) belong to the same W-orbit if and only if they belong to the same irreducible component of Φ and have the same length. Moreover, at most two root lengths (long and short) occur within any irreducible component.

LEMMA 2.1. *Let γ_1, γ_2 be distinct odd roots such that $\langle \gamma_2, \gamma_1^\vee \rangle > 0$.*

  (a) *If γ_1 and γ_2 have the same length, then they belong to the same $W(\Phi_0)$-orbit.*
  (b) *If γ_1 is long and γ_2 is short, then $\gamma_1 = \gamma_2 + \beta$, where $\beta \in \Phi_0$ and $\langle \beta, \gamma_1^\vee \rangle = 1$.*

Proof. In either case, we must have $\langle \gamma_2, \gamma_1^\vee \rangle = 1$ (e.g., [**B**, VI.1.3]). Hence the reflection corresponding to γ_1 maps γ_2 to $-\beta$ where $\beta = \gamma_1 - \gamma_2$ is a necessarily even root of the same length as γ_2. Furthermore, $\langle \beta, \gamma_1^\vee \rangle = \langle \gamma_1 - \gamma_2, \gamma_1^\vee \rangle = 1$, so the conclusions in (b) hold for either case. In (a), the root β also has the same length as γ_1, so $\langle \gamma_1, \beta^\vee \rangle = \langle \beta, \gamma_1^\vee \rangle = 1$ and the (even) reflection corresponding to β maps γ_1 to $\gamma_1 - \beta = \gamma_2$. $\square$

LEMMA 2.2. *Let $\mathcal{O}_1, \mathcal{O}_2$ be $W(\Phi_0)$-orbits generated by odd roots of the same length. If $\mathcal{O}_1 - \mathcal{O}_2 \subset \operatorname{Span} \Phi_0$, then $\mathcal{O}_1 = \pm \mathcal{O}_2$ or $\mathcal{O}_1, \mathcal{O}_2 \subset \operatorname{Span} \Phi_0$.*

Proof. Let $V_0 = \operatorname{Span} \Phi_0$ and assume $\mathcal{O}_1 \neq \pm \mathcal{O}_2$. If we select arbitrary representatives γ_i from $\mathcal{O}_i$, then $\gamma_1 \neq \pm \gamma_2$ and Lemma 2.1(a) (applied to both γ_2 and $-\gamma_2$) shows that γ_1 and γ_2 must be orthogonal. Hence $\operatorname{Span} \mathcal{O}_1$ and $\operatorname{Span} \mathcal{O}_2$ are orthogonal as well. On the other hand, the $W(\Phi_0)$-orbit generated by any vector γ is spanned by γ and the irreducible components of Φ_0 for which the orthogonal projection of γ is nonzero. In particular, the span of such an orbit contains the orthogonal projection of γ onto V_0, and hence the projection onto $V_0^\perp$ as well. However, we are given that $\gamma_1 - \gamma_2 \in V_0$, so γ_1 and γ_2 have the same orthogonal projection onto $V_0^\perp$. Thus the projections cannot be orthogonal unless they are 0; i.e., $\gamma_1, \gamma_2 \in V_0$. $\square$

LEMMA 2.3. *If Φ and Φ_0 have the same rank and Φ is irreducible, then any two odd roots of the same length are in the same $W(\Phi_0)$-orbit.*

Proof. Since Φ and Φ_0 are assumed to have the same rank, every root in Φ must be in the linear span of Φ_0. Thus given any odd root γ that is Φ_0-dominant, we may consider its coordinates with respect to the simple roots of Φ_0, say $\gamma = \sum c_i \beta_i$. One knows that dominance forces $c_i \geqslant 0$ and the support (i.e., $\{i : c_i > 0\}$) must coincide with the union of one or more irreducible components of Φ_0. (This amounts to the fact that the inverse of any irreducible Cartan matrix has strictly positive entries.)

Now suppose that $\gamma_1, \gamma_2, \ldots$ are the Φ_0-dominant members of the distinct $W(\Phi_0)$-orbits of odd roots. If γ_1 and γ_2 have the same length and overlapping support, the dominance forces $\langle \gamma_2, \gamma_1^\vee \rangle > 0$ and we contradict Lemma 2.1(a). In other words, distinct orbits generated by odd roots of the same length have disjoint, orthogonal support.

Alternatively, suppose that γ_1 is long and γ_2 is short. If they have overlapping support, we still have $\langle \gamma_2, \gamma_1^\vee \rangle > 0$ and Lemma 2.1(b) implies that $\gamma_1 = \gamma_2 + \beta$ where β is an even root such that $\langle \beta, \gamma_1^\vee \rangle = 1$. The latter forces β to be positive, since γ_1 is dominant. Thus the support of γ_1 contains the support of γ_2. However, an even root such as β must have support that is confined to a single irreducible component of Φ_0, so if there is a gap between the supports of γ_1 and γ_2, it is this one irreducible component, and β is the orthogonal projection of γ_1 onto this component.

Returning to the hypothesis that γ_1 and γ_2 have the same length, consider that our task is to show that this leads to a contradiction. Since γ_1 and γ_2 must have disjoint orthogonal support and Φ is irreducible, this is possible only if another orbit representative, say γ_3, has support overlapping γ_1 or γ_2 or both. As we have seen, this is possible only if γ_3 is long and γ_1 and γ_2 are short. Since this eliminates the possibility of γ_1 and γ_2 both being long, this means that γ_3 generates the only long odd orbit, and irreducibility forces its support to include the supports of both γ_1 and γ_2. Furthermore, since the supports of γ_1 and γ_2 are disjoint, the inclusions must be proper, and as we have shown, each "support gap" must be a single irreducible component of Φ_0. This forces the support of γ_3 to consist of exactly two irreducible components, and the orthogonal projections of γ_3 onto these two components must be even roots, contradicting the fact that γ_3 is odd. $\square$

PROPOSITION 2.4.

(a) *Every $W(\Phi_0)$-orbit of odd roots includes a simple or a negative simple root.*
(b) *If the nodes of the Dynkin diagram of Φ are 2-colored so that each edge is incident to a black vertex and a white vertex, then the black simple roots and the negatives of the white simple roots in the same W-orbit belong to the same $W(\Phi_0)$-orbit.*
(c) *If Φ is irreducible of rank n, then either*
   (i) *Φ_0 has rank $n-1$, all simple roots of Φ_0 have height 2 in Φ, and every opposite pair of odd roots $\pm\gamma$ belong to distinct $W(\Phi_0)$-orbits, or*
   (ii) *Φ_0 has rank n, one simple root of Φ_0 has height 4 in Φ, and all odd roots of the same length are in the same $W(\Phi_0)$-orbit.*
   Furthermore, case (i) occurs if and only if $\Phi \cong A_n$ or C_n.

Proof. Choose a black-white coloring of the Dynkin diagram as in (b), and assume that Φ is irreducible of rank n. Since the diagram is a tree, there are exactly $n-1$ roots $\beta_1, \ldots, \beta_{n-1}$ of height 2 in Φ; each is of the form $\alpha_i + \alpha_j$ where i is a black node and j is an adjacent white node. If the edge between i and j is simple (i.e., the parabolic subsystem generated by α_i and α_j is isomorphic to A_2), then the reflection corresponding to $\alpha_i + \alpha_j$ interchanges α_i with $-\alpha_j$ and $-\alpha_i$ with α_j. It follows that for any nodes i and j connected by a path of simple edges, the $W(\Phi_0)$-orbit of α_i contains α_j if i and j have the same color, and the orbit contains $-\alpha_j$ if i and j have different colors. On the other hand, it is well-known that two simple (or negative simple) roots belong to the same W-orbit if and only if they are in the same connected component of the Dynkin diagram

after all non-simple edges have been deleted. Thus (b) follows.

Now consider that as a member of the even root system Φ_0, each root β_i is clearly indecomposable (i.e., not expressible as a sum of two positive even roots), and thus is necessarily a simple root of Φ_0. On the other hand, as a root subsystem of a rank n root system, Φ_0 necessarily has rank $\leqslant n$, and thus it can have at most one additional indecomposable root.

Case 1: Φ_0 *has rank* $n-1$.. Define an integral co-weight ω for Φ by setting $\langle \alpha_i, \omega \rangle = 1$ (if i is black) and -1 (if i is white). We therefore have $\langle \beta_i, \omega \rangle = 0$ for all i and hence $W(\Phi_0)$ fixes ω, since $\beta_1, \ldots, \beta_{n-1}$ forms a base for Φ_0 in this case. Thus $\langle \gamma, \omega \rangle$ is a constant as γ varies over any $W(\Phi_0)$-orbit in Φ. For odd γ, this constant is the sum of an odd number of ± 1's, and hence nonzero. Consequently, the $W(\Phi_0)$-orbits of γ and $-\gamma$ are distinct for every odd root γ, proving (i).

We claim that $\langle \gamma, \omega \rangle$ is limited to the values $0, \pm 1$ for all $\gamma \in \Phi$ (i.e., ω is minuscule). Indeed, even roots belong to the hyperplane orthogonal to ω, and if there were an odd root γ such that $\langle \gamma, \omega \rangle \geqslant 3$, then there would be an even root of the form $\beta = \gamma \pm \alpha_i$ for some i. In that case, we would have $\langle \beta, \omega \rangle \geqslant 2$, a contradiction.

Thus every $W(\Phi_0)$-orbit of odd roots belongs to the (affine) hyperplane $\langle \cdot, \omega \rangle = 1$ or its negative, and both hyperplanes contain at least one simple root or negative simple root from each W-orbit. To prove (a) for this case, it therefore suffices to show that all roots of a given length within one of these hyperplanes belong to the same $W(\Phi_0)$-orbit. If there were two such orbits, say $\mathcal{O}_1$ and $\mathcal{O}_2$, then we cannot have $\mathcal{O}_1 = \pm \mathcal{O}_2$ (the orbit opposite to $\mathcal{O}_1$ is in the opposite hyperplane), and yet we do have $\langle \gamma_1 - \gamma_2, \omega \rangle = 0$ for all $\gamma_i \in \mathcal{O}_i$, so Lemma 2.2 implies $\mathcal{O}_i \subset \operatorname{Span} \Phi_0$, a contradiction.

To see that $\Phi = A_n$ and C_n belong to Case 1, it suffices to show that the even roots are confined to a central hyperplane in these cases. For this, let $\varepsilon_1, \ldots, \varepsilon_n$ be the standard orthornomal basis for $\mathbb{R}^n$, and realize C_n using the simple roots $\alpha_1 = 2\varepsilon_1$ and $\alpha_i = \varepsilon_i - \varepsilon_{i-1}$ $(1 < i \leqslant n)$. It is easy to see that $\omega = (1/2)(1, -1, 1, -1, \ldots) \in \mathbb{R}^n$ has the property that $\langle \alpha_i, \omega \rangle = \pm 1$ for all i, so β is even if and only if $\langle \beta, \omega \rangle$ is even. On the other hand, the value $\langle \beta, \omega \rangle$ for any root β is the sum or difference of two coordinates of ω, so the only possible values are 0 and ± 1. That is, β is even if and only if $\langle \beta, \omega \rangle = 0$ and thus Φ_0 is confined to the hyperplane orthogonal to ω. This yields the same result for A_{n-1} if we recognize it as a parabolic subsystem of C_n. That is, the even roots of A_{n-1} are confined to the hyperplane orthogonal to ω in the span of A_{n-1}.

Case 2: Φ_0 *has rank* n. In this case, there must be a positive root $\beta_0 \in \Phi_0$ that has height at least 4 in Φ and is indecomposable in Φ_0. Any such root is necessarily a simple root of Φ_0 and therefore unique, since the height 2 roots already account for all but one of the simple roots of Φ_0. Having previously shown in Lemma 2.3 that length separates the $W(\Phi_0)$-orbits of odd roots in this case, (a) follows immediately. To complete the proof, it suffices to identify an indecomposable even root of height 4 in all remaining irreducible Φ (i.e., other than A_n or C_n). For this, note that all such Φ must have a parabolic subsystem

Φ	A_{2n-1}	A_{2n}	B_n	C_n	D_{2n-1}	D_{2n}	E_6	E_7	E_8	F_4	G_2
$|\Gamma(\Phi_0)|$	2	1	2	2	2	4	1	2	1	1	1
$|W(\Phi_0)\backslash\Phi_1|$	2	2	2	4	1	1	1	1	1	2	2

TABLE 1: The order of $\Gamma(\Phi_0)$ and the $W(\Phi_0)$-orbit count on Φ_1.

isomorphic to D_4, B_3, or G_2.

Case 2(a): Φ *includes a parabolic copy of D_4*. Here, we claim that the sum of the four simple roots in the D_4-subsystem is an indecomposable root β_0 of Φ_0. If not, this root would have to be a sum of two height 2 roots, and hence the diagram of D_4 would have to have two white vertices and two black vertices.

Case 2(b): Φ *includes a parabolic copy of B_3*. Numbering the Dynkin diagram of this subsystem $1{\Leftarrow}2{-}3$, we claim that $\beta_0 = 2\alpha_1 + \alpha_2 + \alpha_3$ is indecomposable in Φ_0. This is immediate after confirming that β_0 is indeed a root, since it is a sum of unequal numbers of white and black simple roots (counted with multiplicity).

Case 2(c): Φ *is isomorphic to G_2*. With the simple roots indexed so that α_1 is short and α_2 is long, the root $\beta_0 = 3\alpha_1 + \alpha_2$ is clearly indecomposable in Φ_0. $\square$

REMARK 2.5. (a) The above result implies that a $W(\Phi_0)$-orbit of odd roots may fail to include a simple root only if Φ is of type A or C and the corresponding W-orbit includes only one simple root. That is, only for one of the long odd orbits in C_n, a long and a short orbit in C_2, and one of the odd orbits in A_1. Most of these orbits do include positive roots, the exceptions being the singleton orbits formed by the short negative simple root of C_2, and the negative simple root of A_1.

(b) To minimize the need for special considerations for the root system $B_2 \cong C_2$, it is preferable to require the type B series of root systems to begin at rank 3 and allow rank 2 only for type C. That way, all type B root systems have only 2 odd orbits, whereas in all type C cases there are 4. See the last row of Table 1.

3. The even normalizer

It will develop that the series $F(\Phi; q)$ depends only on a subgroup $N(\Phi_0)$ of W; namely, the normalizer of $W(\Phi_0)$ in W. Since the W-action on Φ corresponds to the conjugation action of W on reflections, we have that

$$N(\Phi_0) = \{w \in W : w\Phi_0 = \Phi_0\}.$$

Let Δ_0 denote the base formed by the set of simple roots for Φ_0. Since the action of $W(\Phi_0)$ on bases for Φ_0 is simply transitive, the normalizer is a semidirect product; i.e.,

$$N(\Phi_0) \cong W(\Phi_0) \rtimes \Gamma(\Phi_0),$$

where $\Gamma(\Phi_0) := \{w \in W : w\Delta_0 = \Delta_0\}$ is the subgroup of $N(\Phi_0)$ consisting of elements with no even inversions. See Table 1 for the cardinalities of $\Gamma(\Phi_0)$ for irreducible Φ.

The normalizers $N(\Phi_0)$ are closely related to the groups of "chessboard" elements for classical Weyl groups discussed in [**BC1**], [**BC2**], [**KV**], and [**SV1**]. In fact, for the root systems A_n, B_{2n+1}, and D_n they are exactly the same, whereas for B_{2n}, the chessboard group defined in [**BC1**] and [**SV1**] may be seen as the normalizer of a reflection subgroup of W that is slightly larger than $W(\Phi_0)$.

To illustrate the case $\Phi = B_{2n}$ $(n \geqslant 2)$ in more detail, fix simple roots ε_1 and $\varepsilon_i - \varepsilon_{i-1}$ $(1 < i \leqslant 2n)$. From the construction in the proof of Proposition 2.4, one obtains that the simple even roots are ε_2, $\varepsilon_3 + \varepsilon_1$, and $\varepsilon_i - \varepsilon_{i-2}$ $(2 < i \leqslant 2n)$, so Φ_0 decomposes orthogonally into $\{\pm\varepsilon_{2i}, \pm\varepsilon_{2i}\pm\varepsilon_{2j} : i \neq j\} \cong B_n$ and $\{\pm\varepsilon_{2i+1}\pm\varepsilon_{2j+1} : i \neq j\} \cong D_n$. Recognizing that W acts via signed permutations of the coordinates, one sees that $N(\Phi_0) \cong W(B_n) \times W(B_n)$, with the subgroup $\Gamma(\Phi_0)$ being a 2-element group generated by the (simple) reflection corresponding to ε_1. Thus it happens in this case that $N(\Phi_0)$ is also a reflection subgroup of W, and the chessboard group cited above may be seen as its W-normalizer.

REMARK 3.1. (a) The longest element $w_0 = w_0(\Phi)$ in $W(\Phi)$ maps roots of height h to height $-h$, so it preserves parity (i.e., belongs to $N(\Phi_0)$) and maps the simple roots of Φ_0 to some permutation of their negatives. Since $w_0(\Phi_0)$ has a similar effect on the even roots, it follows that $w_0(\Phi_0)w_0(\Phi)$ is always a member of $\Gamma(\Phi_0)$ (possibly trivial).

(b) It is tempting to assume that $\Gamma = \Gamma(\Phi_0)$ acts faithfully as a group of diagram automorphisms of Φ_0, but this isn't true in general—a nontrivial $w \in \Gamma$ may act trivially on Δ_0 and Φ_0. For example, if Φ is C_2, then Φ_0 has rank one and therefore has no nontrivial diagram automorphisms. However, Γ is a 2-element group in this case.

Since $\Gamma(\Phi_0) \cong N(\Phi_0)/W(\Phi_0)$, it follows that $\Gamma(\Phi_0)$ acts on the $W(\Phi_0)$-orbits of odd roots (and generally, the $W(\Phi_0)$-orbits of any $N(\Phi_0)$-action). It will be important in what follows to identify the cases where the action on these orbits is nontrivial.

PROPOSITION 3.2.

    (a) *If Φ is irreducible, then $\Gamma(\Phi_0)$ stabilizes each $W(\Phi_0)$-orbit of odd roots except possibly when $\Phi \cong A_n$ or C_n.*

    (b) *If $\Phi \cong A_{2n}$, then $\Gamma(\Phi_0)$ is trivial.*

    (c) *If $\Phi \cong A_{2n-1}$ or C_n, then $|\Gamma(\Phi_0)| = 2$.*

Moreover, in (c), if the diagram is properly 2-colored so that the black nodes include all end nodes (for A_{2n-1}), or the end node corresponding to a short simple root (for C_n), then the nontrivial element of $\Gamma(\Phi_0)$ is the product of the black simple reflections, and it acts by interchanging opposite pairs $\pm\mathcal{O}$ of $W(\Phi_0)$-orbits of odd roots.

Proof. By Proposition 2.4(c), we know that unless Φ is of type A or C, odd roots in the same W-orbit are also in the same $W(\Phi_0)$-orbit. This proves (a).

For the remaining assertions, we may assume that $\Phi \cong A_n$ or C_n. In such cases, recall from the proof of Proposition 2.4 that there is an integral co-weight ω such that $\langle \alpha_i, \omega \rangle = 1$ if i is black and $\langle \alpha_i, \omega \rangle = -1$ if i is white. (For A_{2n}, any proper 2-coloring will suffice for what follows.) Moreover, the span of Φ_0 is the hyperplane V_0 orthogonal to ω, and hence $W(\Phi_0)$ is the stabilizer of ω.

On the other hand, $N(\Phi_0)$ is the stabilizer of V_0. As a group of orthogonal transformations, it must therefore preserve the orthogonal complement of V_0. Hence

$$N(\Phi_0) = \{x \in W : x\omega = \pm\omega\}.$$

It follows that $|\Gamma(\Phi_0)| \leqslant 2$, with equality if and only if there is an element $x \in W$ such that $x\omega = -\omega$. In that case, x acts on $W(\Phi_0)$-orbits by interchanging opposite pairs.

In the case $\Phi \cong A_{2n}$, if we embed Φ in $\mathbb{R}^{2n+1}$ so that W acts by permuting coordinates, then ω will have $n + 1$ equal positive coordinates and n equal negative coordinates (or vice-versa), and thus no member of W can transform ω to $-\omega$.

For the remaining cases, let $\theta = \sum \alpha_i^\vee$, where i ranges over the black nodes. We claim that $\omega = \theta/2$. To see this, consider that if i is black, then none of its neighbors participate in the sum and $\langle \alpha_i, \theta \rangle = 2$. If j is white, then in most cases it has two neighbors, both black, with corresponding simple roots α_i that are not shorter than α_j. Hence $\langle \alpha_j, \alpha_i^\vee \rangle = -1$ for both neighbors and $\langle \alpha_j, \theta \rangle = -2$. The one exception occurs in C_{2n} when α_j is long, in which case it has only one neighbor i, but $\langle \alpha_j, \alpha_i^\vee \rangle = -2$ and again $\langle \alpha_j, \theta \rangle = -2$. Either way, the claim follows.

Now let x be the product of the black simple reflections. Since these reflections commute, it is clear that $\Phi(x)$ consists of the black simple roots, and it is evident from the co-root coordinates for θ that $x\omega = -\omega$. Hence x belongs to the nontrivial coset of $N(\Phi_0)$. Since it has no even inversions, it is therefore a member of $\Gamma(\Phi_0)$. $\quad\square$

4. Parabolic and multivariate refinements

Let $\mathbf{q} = (q_\beta : \beta \in \Phi_1^+)$ be a collection of variables indexed by the odd positive roots and consider the series

$$F(\Phi; \mathbf{q}) := \sum_{w \in W} \operatorname{sgn}(w) \prod_{\beta \in \Phi_1(w)} q_\beta.$$

Of course we recover the original series $F(\Phi; q)$ by setting $q_\beta = q$ for all $\beta \in \Phi_1^+$. More generally, for each $J \subseteq I$, we will consider the restriction of the above series to the set W^J consisting of the minimum-length coset representatives for W/W_J; i.e.,

$$F_J(\Phi; \mathbf{q}) := \sum_{w \in W^J} \operatorname{sgn}(w) \prod_{\beta \in \Phi_1(w)} q_\beta.$$

One sees that $F_J(\Phi; \mathbf{q}) = F(\Phi; \mathbf{q})$ when $J = \varnothing$.

Although these multivariate series do not seem to offer simple closed forms, the following result shows that a significant amount of cancellation of terms does occur at this level of generality. (One should also note that this feature is specific to sums over left cosets. The analogous sum over ^JW offers no comparable degree of cancellation, and specializations of such sums appear to factor less often than the left coset series. See Remark 7.6.)

PROPOSITION 4.1. *For all $J \subseteq I$, we have*

$$F_J(\Phi; \mathbf{q}) = \sum_{w \in N(\Phi_0) \cap W^J} \mathrm{sgn}(w) \prod_{\beta \in \Phi_1(w)} q_\beta.$$

This justifies our prior claim that $F(\Phi; q)$ depends only on the normalizer $N(\Phi_0)$.

For the proof, choose a fixed total ordering of the index set I. Given $w \in W$ such that $w \notin N(\Phi_0)$, we define the *first fault* of w to be the least $i \in I$ such that $w^{-1}\alpha_i$ is even. Such an index i must exist, otherwise, w^{-1} would map all simple roots to odd roots, and thus w^{-1} and w would be parity preserving on roots; i.e., members of $N(\Phi_0)$.

LEMMA 4.2. *If $w \in W^J$ and $w^{-1}\alpha_i$ is even for some $i \in I$, then $s_i w \in W^J$. Furthermore, if i is the first fault of w, then i is also the first fault of $s_i w$.*

Proof. If $s_i w \notin W^J$, then there is some index $j \in J$ such that $\ell(s_i w s_j) < \ell(s_i w)$. Thus either $\ell(w) = \ell(s_i w s_j)$ or $\ell(w) = \ell(s_i w s_j) + 2$. In the latter case, w has a reduced expression that ends with s_j, contradicting the fact that $w \in W^J$. In the former case, the Deletion Property [**H**, §1.7] implies that a reduced expression for $s_i w s_j$ may be obtained by taking a reduced expression for w, appending s_j, prepending s_i, and deleting two terms. If one or both of the deleted terms is internal to the chosen expression for w, then w would have a reduced expression that begins with s_i or ends with s_j. The latter contradicts the fact that $w \in W^J$, and the former contradicts the fact that $\ell(s_i w) > \ell(w)$ in this case. The remaining possibility is that the first and last terms are deleted; i.e., $s_i w s_j = w$, or equivalently, $w^{-1}\alpha_i = \pm\alpha_j$. However, this contradicts the fact that $w^{-1}\alpha_i$ is even.

For the second claim, consider that for all indices $k \in I$, we have

$$(s_i w)^{-1}\alpha_k = w^{-1}s_i\alpha_k = w^{-1}\alpha_k - aw^{-1}\alpha_i$$

where a is the integer $\langle \alpha_k, \alpha_i^\vee \rangle$. Thus if i is the first fault of w, it follows that $(s_i w)^{-1}\alpha_k$ is even if and only if $w^{-1}\alpha_k$ is even. In particular, i must be the first fault of $s_i w$. $\square$

Proof of Proposition 4.1. Lemma 4.2 implies that the map $w \mapsto s_i w$ (with i being the first fault of w) defines a sign-reversing involution on the members of W^J not in $N(\Phi_0)$. Exchanging w with $s_i w$ if necessary, we may assume that $\ell(s_i w) > \ell(w)$. In that case,

$$\Phi(s_i w) = \Phi(w) \;\dot\cup\; \{w^{-1}\alpha_i\}.$$

Thus the inversion sets of w and $s_i w$ are identical aside from a single even root, so their contributions to the sum cancel out, leaving only the contributions from $N(\Phi_0) \cap W^J$. $\square$

REMARK 4.3. We have previously noted that the longest element w_0 is the unique member of W that inverts all odd roots. Since $\Phi(w) \subseteq \Phi^+ \setminus \Phi_J$ for all $w \in W^J$, we thus have the degree bound

$$\deg F_J(\Phi; q) \;\leqslant\; |\Phi_1^+ \setminus \Phi_J| \;=\; \deg F(\Phi; q) - \deg F(\Phi_J; q).$$

Furthermore, there may be multiple members of W^J that invert all of $\Phi_1^+ \setminus \Phi_J$, resulting in the possibility of cancellation and a degree that does not achieve this bound. For example, when $(\Phi, \Phi_J) \cong (D_4, A_1^{\oplus 3})$, there are 5 odd positive roots not in Φ_J, but it is easily checked that $F_J(D_4; q) = (1 - q^2)(1 + 3q^2)$. This also shows that the irreducible factors of $F_J(\Phi; q)$ need not be cyclotomic.

From now on, we will focus on three specializations of the variables q_β; namely,

(i) The univariate grading; i.e., q_β is independent of β.
(ii) The coarse grading; i.e., q_β depends only on the W-orbit of β.
(iii) The fine grading; i.e., q_β depends only on the $W(\Phi_0)$-orbit of β.

By Proposition 2.4, we know that in most irreducible cases, each W-orbit of roots contains only one $W(\Phi_0)$-orbit of odd roots, and hence, the coarse and fine gradings coincide. The exceptions are A_n (which has two $W(\Phi_0)$-orbits of odd roots) and C_n (which has four; two long and two short). Among these exceptions, A_1 and C_2 are somewhat degenerate in having an odd $W(\Phi_0)$-orbit that consists only of negative roots. (Recall Remark 2.5(a).) The corresponding series $F(\Phi; \mathbf{q})$ under the fine grading therefore depends on only 1 or 3 variables, rather than 2 or 4, respectively.

5. Perfect cosets and divisibility

Fix $J \subseteq I$ and consider a minimal right coset representative $y \in {}^J W$. Recall that this means $\ell(s_j y) > \ell(y)$ for all $j \in J$, or equivalently $y^{-1}\alpha_j > 0$ for such j. We say that y is *perfect* if, in addition, $y^{-1}\alpha_j$ is odd for all $j \in J$. (Thus in the terminology of the previous section, the perfect members of ${}^J W$ have no faults in J.) We let

$$ {}^J W_1 := \{ y \in W : y^{-1}\alpha_j \in \Phi_1^+ \text{ for all } j \in J \} $$

denote the set of minimal coset representatives that are perfect, and

$$ G_J(\Phi; \mathbf{q}) := \sum_{y \in {}^J W_1} \operatorname{sgn}(y) \prod_{\beta \in \Phi_1(y)} q_\beta $$

the corresponding sign-twisted series.

THEOREM 5.1. *For all $J \subseteq I$, we have*

$$F(\Phi; \mathbf{q}) = \sum_{y \in {}^J W_1} \left(\mathrm{sgn}(y) \prod_{\beta \in \Phi_1(y)} q_\beta \right) F(\Phi_J; y^{-1}\mathbf{q})$$

under the fine[1]*grading for Φ, where $y^{-1}\mathbf{q}$ denotes the change of variable $q_\beta \to q_{y^{-1}\beta}$ for odd $\beta \in \Phi_J^+$. In particular, if $F(\Phi_J; y^{-1}\mathbf{q}) = F(\Phi_J; \mathbf{q})$ for all $y \in {}^J W_1$, then*

$$F(\Phi; \mathbf{q}) = G_J(\Phi; \mathbf{q}) F(\Phi_J; \mathbf{q})$$

under the fine grading for Φ.

Note that if y is perfect and $\beta \in \Phi_J$ is odd, then $y^{-1}\beta$ is clearly another odd root in the same W-orbit. Hence, for the coarse specialization of the variables q_β, we have

COROLLARY 5.2. *In all cases, $F(\Phi; \mathbf{q}) = G_J(\Phi; \mathbf{q}) F(\Phi_J; \mathbf{q})$ under the coarse grading.*

Thus it is clear *a priori* (i.e., without use of the classification of finite root systems, or explicit evaluation) that $F(\Phi; \mathbf{q})$ has many divisors under the coarse grading, and therefore is likely to have a nice factorization.

For the finer gradings available with A_n and C_n, it need not be the case that $F(\Phi; \mathbf{q})$ is divisible by $F(\Phi_J; \mathbf{q})$. For example, *a posteriori* (see Theorem 6.1 below) $F(A_n; \mathbf{q})$ is divisible by $F(A_k; \mathbf{q})$ under the fine grading only if k is even, or n is odd and $k+1$ divides $n + 1$. On the other hand, the following result shows that A_n and C_n have parabolic subsystems of co-rank at most 2 where divisibility is clear *a priori*.

COROLLARY 5.3. *If $\Phi_J \cong A_{2n}$, then $F(\Phi; \mathbf{q}) = G_J(\Phi; \mathbf{q}) F(\Phi_J; \mathbf{q})$ in the fine grading.*

Proof. For perfect $y \in {}^J W$, the map $\beta \mapsto y^{-1}\beta$ acts as a parity-preserving isomorphism between two copies of A_{2n} embedded in Φ (namely, Φ_J and $y^{-1}\Phi_J$). Although it is possible that β and $y^{-1}\beta$ are in distinct $W(\Phi_0)$-orbits for odd $\beta \in \Phi_J$, there is a diagram automorphism of A_{2n} that interchanges the black and white vertices of the 2-colored Dynkin diagram. By Proposition 2.4, it follows that this automorphism interchanges the two orbits of odd roots, and thus $F(A_{2n}; \mathbf{q})$ is invariant under interchanging the variables q_β in these two orbits. Thus either way, we have $F(\Phi_J; y^{-1}\mathbf{q}) = F(\Phi_J; \mathbf{q})$ for all y. $\square$

Proof of Theorem 5.1. Suppose that $y \in {}^J W$ is not perfect, so that there is some $j \in J$ such that $\beta = y^{-1}\alpha_j$ is an even (necessarily positive) root. Since $\ell(xy) = \ell(x) + \ell(y)$ for all $x \in W_J$, Lemma 1.1 implies

$$\Phi(xy) = \Phi(y) \,\dot\cup\, y^{-1}\Phi(x). \tag{5.1}$$

---

[1]Note that the fine grading for Φ may force the identification of some variables appearing in $F(\Phi_J; \mathbf{q})$ that would otherwise be distinct in the fine grading for Φ_J.

Replacing x with xs_j if necessary so that $\ell(xs_j) > \ell(x)$, we also have

$$\Phi(xs_jy) = \Phi(y) \,\dot\cup\, \{y^{-1}\alpha_j\} \,\dot\cup\, y^{-1}s_j\Phi(x) = \Phi(y) \,\dot\cup\, \{\beta\} \,\dot\cup\, ty^{-1}\Phi(x),$$

where $t = y^{-1}s_jy$ is the reflection corresponding to β. Since β is even, t belongs to $W(\Phi_0)$, so for each $W(\Phi_0)$-orbit of odd roots, the number of such roots in $y^{-1}\Phi(x)$ and $ty^{-1}\Phi(x)$ is the same. It follows that the contributions of xy and xs_jy to the series $F(\Phi; \mathbf{q})$ cancel out, and thus the net contribution of the coset W_Jy is zero.

For perfect y, we still have (5.1), whence

$$\sum_{x \in W_J} \mathrm{sgn}(xy) \prod_{\beta \in \Phi_1(xy)} q_\beta = \mathrm{sgn}(y)F(\Phi_J; y^{-1}\mathbf{q}) \prod_{\beta \in \Phi_1(y)} q_\beta$$

and the result follows. $\square$

Let $\rho^\vee$ be the unique co-weight such that $\langle\alpha_i, \rho^\vee\rangle = 1$ for all $i \in I$. (It is well-known that $2\rho^\vee$ is also the sum of all positive co-roots.) We have found that the most convenient way to explicitly compute $G_J(\Phi; \mathbf{q})$ under the coarse grading is as follows.

PROPOSITION 5.4. *Let $\Phi = \mathcal{O}_1 \,\dot\cup\, \mathcal{O}_2 \,\dot\cup\, \cdots$ be the partition of Φ into W-orbits, and choose variables q_i so that $q_i = q_\beta$ for all $\beta \in \mathcal{O}_i \cap \Phi_1^+$.*

(a) *The map $w \mapsto w\rho^\vee$ defines a bijection between the set ${}^JW_1$ of perfect coset representatives and*

$$(W\rho^\vee)_J := \{\theta \in W\rho^\vee : \langle\alpha_j, \theta\rangle \text{ is odd and positive for all } j \in J\}.$$

(b) *Under the coarse grading, we have*

$$G_J(\Phi; \mathbf{q}) = \sum_{\theta \in (W\rho^\vee)_J} (-1)^{N(\theta)} q_1^{N_1(\theta)} q_2^{N_2(\theta)} \cdots,$$

where $N(\theta) := |\{\beta \in \Phi^+ : \langle\beta, \theta\rangle < 0\}|$ and

$$N_i(\theta) := |\{\beta \in \mathcal{O}_i \cap \Phi^+ : \langle\beta, \theta\rangle \text{ is odd and negative}\}|.$$

Note that the roots β contributing to $N_i(\theta)$ may be odd or even.

Proof. (a) Recall that $w \in {}^JW_1$ if and only if $w^{-1}\alpha_j$ is odd and positive for all $j \in J$. On the other hand, the height of a root β is $\langle\beta, \rho^\vee\rangle$, so $\langle\alpha_j, w\rho^\vee\rangle = \langle w^{-1}\alpha_j, \rho^\vee\rangle$ is odd and positive if and only if $w^{-1}\alpha_j$ is odd and positive. Since $\rho^\vee$ is regular, the map $w \mapsto w\rho^\vee$ is injective, and the claim follows.

(b) Given $\theta = w\rho^\vee$ and a root β, we have $\langle\beta, \theta\rangle = \langle w^{-1}\beta, \rho^\vee\rangle$, so

$$\Phi(w) = \{-w^{-1}\beta : \beta \in \Phi^+, \langle\beta, \theta\rangle < 0\}$$

and $N(\theta)$ is the total number of inversions for w; i.e., $N(\theta) = \ell(w)$. Since β and $-w^{-1}\beta$ clearly belong to the same W-orbit, and $-w^{-1}\beta$ is odd if and only if $\langle\beta, \theta\rangle$ is odd, we obtain that $N_i(\theta)$ is the number of odd inversions for w in the W-orbit $\mathcal{O}_i$. $\square$

$\langle w\rho^\vee, \alpha_i\rangle, i=1,\ldots,8$	$\ell(w)$	$\ell_1(w)$	$\langle w\rho^\vee, \alpha_i\rangle, i=1,\ldots,8$	$\ell(w)$	$\ell_1(w)$

TABLE 2: Perfect coset representatives for $W(E_7)\backslash W(E_8)$.

REMARK 5.5. (a) Determining the points in the W-orbit of $\rho^\vee$ that correspond to the perfect cosets for $W_J\backslash W$ does not require generating the entire orbit. Indeed, we claim that it is possible to efficiently generate the much smaller set $^JW\rho^\vee$ consisting of members of the orbit that are Φ_J-dominant, and select from these the ones that are perfect. Indeed, we claim that $^JW\rho^\vee$ is the smallest set X of co-weights that

(1) contains $\rho^\vee$, and
(2) contains $\theta - \beta^\vee$ if $\theta \in X$, $\beta \in \Phi^+ \setminus \Phi_J$, $\langle \beta, \theta\rangle = 1$, and $\theta - \beta^\vee$ is Φ_J-dominant.

Given that θ and β satisfy the hypotheses for (2), it follows that $\theta - \beta^\vee$ is the image of θ under the reflection corresponding to β. Thus the fact that $^JW\rho^\vee$ contains X follows by induction with respect to height. Conversely, given $w \in {}^JW$, either $w = 1$ and $w\rho^\vee = \rho^\vee$, or we have $\ell(ws_i) < \ell(w)$ and $\beta = -w\alpha_i > 0$ for some i. We must also have $\beta \notin \Phi_J$, otherwise $ws_iw^{-1} \in W_J$ and $\ell(ws_i) = \ell(ws_iw^{-1}\cdot w) > \ell(w)$, a contradiction. Furthermore, it must be the case that $ws_i \in {}^JW$. Otherwise, for some $j \in J$ we would have

$$\ell(s_jws_i) < \ell(ws_i) < \ell(w) < \ell(s_jw),$$

contradicting the fact that s_jws_i and s_jw differ in length by 1. Thus by induction with respect to length, we may assume $ws_i\rho^\vee \in X$. However, $ws_i\rho^\vee = w(\rho^\vee - \alpha_i^\vee) = w\rho^\vee + \beta^\vee$ and $\langle \beta, ws_i\rho^\vee\rangle = \langle \alpha_i, \rho^\vee\rangle = 1$, whence $ws_i\rho^\vee - \beta^\vee = w\rho^\vee \in X$ by (2).

(b) For example, if $(\Phi, \Phi_J) \cong (E_8, E_7)$, then there are only 240 cosets for $W_J \backslash W$ (one for each root), and it is a fast calculation to generate the 240 vectors in $^J W \rho^\vee$ by the above algorithm. It turns out that 32 of the 240 vectors correspond to cosets whose minimal representatives are perfect. In Table 2, we list the co-weight coordinates of these 32 vectors; i.e., for each $w \in {}^J W_1$, we list $\langle w\rho^\vee, \alpha_i \rangle$ for $1 \leqslant i \leqslant 8$, along with $\ell(w) = N(w\rho^\vee)$ and $\ell_1(w) = N_1(w\rho^\vee)$ (cf. the formulas in Proposition 5.4(b)).

Note that we have indexed the simple roots of E_8 as in this Dynkin diagram:

$$
\begin{array}{c}
2 \\
| \\
1{-}3{-}4{-}5{-}6{-}7{-}8.
\end{array}
$$

The fact that the first 7 coordinates are odd and positive in each of the 32 cases confirms that these correspond to minimal coset representatives that are perfect.

6. Factoring the fine graded series

Following the road map laid out in the previous section, we are now in a position to explicitly evaluate the fine or coarse graded series for each irreducible root system. To set a convention for naming the variables for the coarse grading, let

- $q_\beta = q$ if Φ is of type A, D, or E,
- $q_\beta = p$ (if β is short) or q (if β is long) for B_n, F_4, and G_2, and
- $q_\beta = q$ (if β is short) or r (if β is long) for C_n

for all odd positive roots β. In this way, the variable attached to an odd root in A_{n-1} is unchanged when A_{n-1} is embedded as a parabolic subsystem of B_n or C_n.

In types A and C, where each W-orbit of roots contains two $W(\Phi_0)$-orbits of odd roots (Proposition 2.4), we will use the variables $q_\pm$ and $r_\pm$ for the fine grading. For C_n, the $W(\Phi_0)$-orbit containing the long simple root will be weighted r_+, and the short simple root that is adjacent to it in the Dynkin diagram will be weighted q_+. For A_{2n-1}, the odd orbit containing the simple roots at both ends of the Dynkin diagram will be weighted q_+. For A_{2n}, we have noted previously that the diagram automorphism interchanges the two $W(\Phi_0)$-orbits of odd roots, so the fine series is unaffected by the choice of which one is weighted q_+; either choice will suffice despite being non-canonical.

For the fine series, it will be convenient to let $\mathbf{q} \to \bar{\mathbf{q}}$ denote the transformation of the variables in which the value of q_β on a $W(\Phi_0)$-orbit $\mathcal{O}$ is replaced by its value on the opposite orbit $-\mathcal{O}$. For A_n and C_n, this amounts to interchanging q_+ with q_- and r_+ with r_-. In particular, as noted above,

$$
F(A_{2n}; \mathbf{q}) = F(A_{2n}; \bar{\mathbf{q}}). \tag{6.1}
$$

Of course in the other irreducible cases, we know that every $W(\Phi_0)$-orbit is centrally symmetric ($\mathcal{O} = -\mathcal{O}$) and this transformation has no effect (Proposition 2.4).

In the following, we let $(a; q)_n = (1 - a)(1 - aq) \cdots (1 - aq^{n-1})$.

THEOREM 6.1. *For the finely graded series, we have*

$$F(A_{2n-1}; \mathbf{q}) = (1 - q_+^n)(q_+q_-; q_+q_-)_{n-1},$$

$$F(A_{2n}; \mathbf{q}) = (q_+q_-; q_+q_-)_n,$$

$$F(B_{2n}; \mathbf{q}) = (q^2; q^2)_n (p; q^2)_n,$$

$$F(B_{2n+1}; \mathbf{q}) = (q^2; q^2)_n (p; q^2)_{n+1},$$

$$F(C_{2n}; \mathbf{q}) = (1 - q_+^n)(q_+q_-; q_+q_-)_{n-1}(r_+r_-; q_+q_-)_n,$$

$$F(C_{2n+1}; \mathbf{q}) = (1 - r_+q_-^n)(q_+q_-; q_+q_-)_n (r_+r_-; q_+q_-)_n,$$

$$F(D_{2n}; \mathbf{q}) = (1 - q^n)^2 (q^2; q^2)_{n-1}^2,$$

$$F(D_{2n+1}; \mathbf{q}) = (q^2; q^2)_n^2,$$

$$F(E_6; \mathbf{q}) = (q^2; q^2)_4,$$

$$F(E_7; \mathbf{q}) = (q^2; q)_7,$$

$$F(E_8; \mathbf{q}) = (1 - q^8)(q^2; q^2)_7,$$

$$F(F_4; \mathbf{q}) = (1 - p^2)(1 - q^2)(1 - p^2 q^2)(1 - p^2 q^4),$$

$$F(G_2; \mathbf{q}) = (1 - p^2)(1 - q^2).$$

Proof. Proceed by induction with respect to rank. In most cases, the claimed identity may be proved by using Proposition 5.4 to compute the series $G_J(\Phi; \mathbf{q})$ for a suitable parabolic subsystem Φ_J of co-rank 1, and then appealing to Corollary 5.2 and the induction hypothesis. However, for A_n and C_n, our induction will directly rely on Theorem 5.1.

Case 1: $\Phi = A_n$. With coordinates chosen so that $\alpha_i = \varepsilon_{i+1} - \varepsilon_i$ ($1 \leqslant i \leqslant n$), the co-weight $\rho^\vee$ is the orthogonal projection of $(0, 1, \ldots, n)$ into the hyperplane normal to $(1, \ldots, 1)$. The W-orbit of $\rho^\vee$ may thus be identified with the permutations of $\{0, \ldots, n\}$. If $\Phi_J \cong A_{n-1}$ omits the first simple root, then the members of this orbit that are Φ_J-dominant are of the form $(a_0, \ldots, a_n)$ with $a_1 < \cdots < a_n$, and the ones that correspond to perfect cosets (see Proposition 5.4(a)) must also have $a_{i+1} - a_i$ odd for all $i \geqslant 1$. Only two permutations satisfy this property: $(0, 1, \ldots, n)$ and $(n, 0, \ldots, n - 1)$. Thus there are only two perfect coset representatives: the identity element and $y = s_1 s_2 \ldots s_n$. Of course y has n inversions; the odd ones are the roots $\varepsilon_{n+1} - \varepsilon_i = \alpha_n + \cdots + \alpha_i$ for $i = n \bmod 2$. These all belong to the $W(\Phi_0)$-orbit of α_n. If n is odd, then these inversions are all weighted q_+, and Corollary 5.3 yields

$$F(A_{2n-1}; \mathbf{q}) = (1 - q_+^n) F(A_{2n-2}; \mathbf{q}). \tag{6.2}$$

For even n, there is no harm in declaring the odd root α_n to have weight q_+ (recall (6.1)). This agrees with the weight it is assigned as a member of Φ_J. However, it is the opposite

of the weight assigned to $y^{-1}\alpha_n = \alpha_{n-1}$, so the effect of the substitution $\mathbf{q} \to y^{-1}\mathbf{q}$ on $F(\Phi_J; \mathbf{q})$ is the change of variables $\mathbf{q} \to \bar{\mathbf{q}}$. Thus Theorem 5.1 in this case implies

$$
\begin{aligned}
F(A_{2n}; \mathbf{q}) &= F(A_{2n-1}; \mathbf{q}) + q_+^n F(A_{2n-1}; \bar{\mathbf{q}}) \\
&= (1 - q_+^n) F(A_{2n-2}; \mathbf{q}) + q_+^n (1 - q_-^n) F(A_{2n-2}; \mathbf{q}) \\
&= (1 - q_+^n q_-^n) F(A_{2n-2}; \mathbf{q}),
\end{aligned}
$$

the second equality being a consequence of (6.1) and (6.2).

Case 2: $\Phi = B_n$. By choosing simple roots $\alpha_1 = \varepsilon_1$ and $\alpha_i = \varepsilon_i - \varepsilon_{i-1}$ ($1 < i \leqslant n$), we have $\rho^\vee = (1, 2, \ldots, n)$. The W-orbit of $\rho^\vee$ consists of all signed permutations of $\{1, \ldots, n\}$, and with $\Phi_J \cong B_{n-1}$ omitting the simple root α_n, one sees that a member $(a_1, \ldots, a_n)$ of this orbit is Φ_J-dominant when $0 < a_1 < \cdots < a_{n-1}$. Imposing the additional constraints in Proposition 5.4(a) (i.e., $a_i = i \bmod 2$), we see that there is only one nontrivial member of this orbit that corresponds to a perfect coset; namely, $\theta = (1, \ldots, n-1, -n)$. Since

$$
\{\beta \in \Phi^+ : \langle \beta, \theta \rangle < 0\} = \{\varepsilon_n\} \cup \{\varepsilon_n \pm \varepsilon_i : i < n\},
$$

one infers that this coset representative has $2n - 1$ inversions. Among these roots, we have $\langle \beta, \theta \rangle$ odd if and only if $\beta = \varepsilon_n$ and n is odd, or $\beta = \varepsilon_n \pm \varepsilon_i$ and $i \neq n \bmod 2$. Thus Proposition 5.4 and Corollary 5.2 imply

$$
F(B_n; \mathbf{q}) / F(B_{n-1}; \mathbf{q}) = \begin{cases} 1 - pq^{n-1} & \text{if } n \text{ is odd,} \\ 1 - q^n & \text{if } n \text{ is even.} \end{cases}
$$

For the base of this induction, one may specialize the series for C_2.

Case 3: $\Phi = C_n$. With simple roots $\alpha_1 = 2\varepsilon_1$ and $\alpha_i = \varepsilon_i - \varepsilon_{i-1}$ ($1 < i \leqslant n$), one has $2\rho^\vee = (1, 3, \ldots, 2n-1)$. The W-orbit of $2\rho^\vee$ consists of all signed permutations of these coordinates, and with J chosen so that $\Phi_J \cong C_{n-1}$, the condition for a member $(a_1, \ldots, a_n)$ of this orbit to be Φ_J-dominant is $0 < a_1 < \cdots < a_{n-1}$. After accounting for the extra factor of 2, the perfection constraints of Proposition 5.4(a) amount to the added condition that $a_i - a_{i-1} = 2 \bmod 4$ for $1 < i < n$, leaving four possibilities:

$$
(1, 3, \ldots, 2n-3, \pm(2n-1)), \quad (3, 5, \ldots, 2n-1, \pm 1).
$$

The corresponding perfect coset representatives are

$$
{}^J W_1 = \{1, \ y, \ ys_1, \ ys_1 y^{-1}\},
$$

where $y = s_n \cdots s_3 s_2$. Thus there are four terms in the recurrence for $F(C_n; \mathbf{q})$ provided by Theorem 5.1. Of course the term contributed by the identity element is $F(C_{n-1}; \mathbf{q})$. For the remaining three, the inversion sets are

$$
\Phi(y) = \{\varepsilon_i - \varepsilon_1 : 1 < i \leqslant n\}, \quad \Phi(ys_1) = \{\varepsilon_i + \varepsilon_1 : 1 \leqslant i \leqslant n\},
$$
$$
\Phi(ys_1 y^{-1}) = \Phi^+ \setminus \Phi_J = \{2\varepsilon_n\} \cup \{\varepsilon_n \pm \varepsilon_i : 1 \leqslant i < n\}.
$$

Now recall from the proof of Proposition 2.4 that $\beta \in C_n$ is odd if and only if $\langle \beta, \omega \rangle = \pm 2$, where $\omega = (1, -1, 1, -1, \ldots)$. Moreover, our conventions for the variables q_β are such that if $\langle \beta, \omega \rangle = 2$, then $q_\beta = r_+$ (if β is long) or q_- (if β is short).

Hence the odd inversions for $y s_1 y^{-1}$ are $\varepsilon_n + \varepsilon_i$ (for $i = n \bmod 2$), $\varepsilon_n - \varepsilon_i$ (for $i \neq n \bmod 2$), and $2\varepsilon_n$. These have weights q_+ and r_- for n even, or q_- and r_+ for n odd. Since $y s_1 y^{-1}$ acts trivially on Φ_J, we conclude that this term contributes $-r_- q_+^{n-1} F(C_{n-1}; \mathbf{q})$ for n even or $-r_+ q_-^{n-1} F(C_{n-1}; \mathbf{q})$ for n odd.

Similarly, the odd inversions for y are $\varepsilon_{2i} - \varepsilon_1$ (all of weight q_+), and for $y s_1$ they are $2\varepsilon_1$ (of weight r_+) and $\varepsilon_{2i+1} + \varepsilon_1$ (of weight q_-). Furthermore, $y^{-1} \alpha_1 = (y s_1)^{-1} \alpha_1 = 2\varepsilon_2$ and $y^{-1} \alpha_2 = (y s_1)^{-1} \alpha_2 = \alpha_3$, so the substitutions $\mathbf{q} \to y^{-1} \mathbf{q}$ and $\mathbf{q} \to (y s_1)^{-1} \mathbf{q}$ are equivalent to the change of variable $\mathbf{q} \to \bar{\mathbf{q}}$. Thus Theorem 5.1 implies

$$F(C_{2n}; \mathbf{q}) = (1 - r_- q_+^{2n-1}) F(C_{2n-1}; \mathbf{q}) + (r_+ q_-^{n-1} - q_+^n) F(C_{2n-1}; \bar{\mathbf{q}}),$$

$$F(C_{2n+1}; \mathbf{q}) = (1 - r_+ q_-^{2n}) F(C_{2n}; \mathbf{q}) - (r_+ q_-^n - q_+^n) F(C_{2n}; \bar{\mathbf{q}}).$$

After isolating common factors, one sees that having the claimed product formula for $F(C_n; \mathbf{q})$ satisfy the above recurrence reduces to confirming the pair of identities

$$(1 - q_+^n)(1 - r_+ r_- q_+^{n-1} q_-^{n-1}) = (1 - r_- q_+^{2n-1})(1 - r_+ q_-^{n-1}) + (r_+ q_-^{n-1} - q_+^n)(1 - r_- q_+^{n-1}),$$

$$(1 - r_+ q_-^n)(1 - q_+^n q_-^n) = (1 - r_+ q_-^{2n})(1 - q_+^n) - (r_+ q_-^n - q_+^n)(1 - q_-^n).$$

After checking directly that $F(C_2; \mathbf{q}) = (1 - q_+)(1 - r_+ r_-)$, this induction is complete.

Case 4: $\Phi = D_n$. With simple roots $\alpha_1 = \varepsilon_1 + \varepsilon_2$ and $\alpha_i = \varepsilon_i - \varepsilon_{i-1}$ ($1 < i \leqslant n$), one has $\rho^\vee = (0, 1, \ldots, n-1)$. The W-orbit of $\rho^\vee$ consists of all signed permutations of these coordinates, and with $\Phi_J \cong D_{n-1}$ omitting the simple root α_n, one sees that a member $(a_1, \ldots, a_n)$ of this orbit is Φ_J-dominant when $|a_1| < a_2 < \cdots < a_{n-1}$. The perfection constraints in Proposition 5.4(a) require $a_i - a_{i-1}$ to be odd for $1 < i < n$, yielding four points in $(W\rho^\vee)_J$; namely,

$$\theta_{\pm 1} = (\pm 1, 2, \ldots, n-1, 0), \quad \theta_{\pm n} = (0, 1, \ldots, n-2, \pm(n-1)).$$

Of course $\theta_n = \rho^\vee$ contributes 1 to $G_J(\Phi; \mathbf{q})$. In the remaining cases, the roots in $\Phi^+ \setminus \Phi_J$ are of the form $\varepsilon_n \pm \varepsilon_i$ for $i < n$, and we have

$$\langle \varepsilon_n \pm \varepsilon_i, \theta_1 \rangle = \pm i, \quad \langle \varepsilon_n \pm \varepsilon_i, \theta_{-n} \rangle = -(n-1) \pm (i-1).$$

The results for θ_{-1} are similar to θ_1 except that the values for $\varepsilon_n \pm \varepsilon_1$ are swapped. Thus the coset representatives corresponding to $\theta_{\pm 1}$ and θ_{-n} have $n-1$ and $2(n-1)$ inversions, respectively. The negative odd evaluations for $\theta_{\pm 1}$ occur once for each odd i, and for θ_{-n} they occur twice for each $i \neq n \bmod 2$. Thus Proposition 5.4 and Corollary 5.2 imply

$$F(D_{2n}; \mathbf{q})/F(D_{2n-1}; \mathbf{q}) = (1 - q^n)^2, \quad F(D_{2n+1}; \mathbf{q})/F(D_{2n}; \mathbf{q}) = (1 + q^n)^2.$$

For the base of this induction, one may use the univariate series for $A_3 \cong D_3$.

Case 5. The remaining possibilities are the five exceptional root systems. For G_2, it is probably easiest to evaluate the series directly either via Proposition 4.1 or the definition. We leave this to the reader. For $\Phi = F_4$, E_6, E_7, and E_8, we will give a high-level description of the computation.

First, we choose parabolic subsystems Φ_J isomorphic to B_3, D_5, E_6, and E_7 (respectively), and generate the Φ_J-dominant portion of the W-orbit of $\rho^\vee$ via the algorithm in Remark 5.5. The respective sizes of these sets are 24, 27, 56, and 240.

It is then an easy computation to select from these sets the vectors $\theta = w\rho^\vee$ that satisfy the perfection constraints of Proposition 5.4(a) (i.e., θ such that $\langle \theta, \alpha_j \rangle$ is odd and positive for all $j \in J$). One obtains 6, 6, 8, and 32 such vectors, respectively.

Coordinates for the 32 vectors arising in the case of E_8 were provided in Table 2.

Once the vectors have been collected, it is a routine application of Proposition 5.4 and Corollary 5.2 to compute $F(\Phi; \mathbf{q})/F(\Phi_J; \mathbf{q})$. One obtains

$$F(F_4; \mathbf{q})/F(B_3; \mathbf{q}) = (1+p)(1+pq^2)(1-p^2q^2),$$
$$F(E_6; \mathbf{q})/F(D_5; \mathbf{q}) = (1+q^4)(1+q^2+q^4),$$
$$F(E_7; \mathbf{q})/F(E_6; \mathbf{q}) = (1-q^3)(1-q^5)(1-q^7),$$
$$F(E_8; \mathbf{q})/F(E_7; \mathbf{q}) = (1-q^8)(1+q^3)(1+q^5)(1+q^6)(1+q^7). \quad \square$$

REMARK 6.2. As mentioned in the introduction, the univariate series $F(\Phi; q)$ except for the case $\Phi = E_8$ were determined previously by Brenti and Carnevale in [**BC2**] (see also the references cited there for earlier work in special cases). It is interesting to note that they give multivariate refinements of the coarse graded series for B_n and C_n that use 3 and 4 variables, respectively. (See Theorem 5.5 and the first formula in Theorem 5.7 in [**BC2**].) Curiously, their 4 variable series for C_n and our 4 variable fine graded series do not record the same information about the distribution of odd inversions.

7. The parabolic series

We now turn our attention to the parabolic series $F_J(\Phi; \mathbf{q})$ introduced in Section 4. We will say that a subsystem $\Phi_J \subset \Phi$ is *coherent* whenever

$$F_J(\Phi; \mathbf{q}) = F(\Phi; \mathbf{q})/F(\Phi_J; \mathbf{q}) \tag{7.1}$$

under the fine grading. Since we have explicit formulas for the full series, we therefore have explicit formulas for $F_J(\Phi; \mathbf{q})$ whenever Φ_J is coherent.

Of course it cannot generally be the case that all subsystems are coherent. For example, we have previously noted that the quotient $F(\Phi; \mathbf{q})/F(\Phi_J; \mathbf{q})$ need not even be a polynomial in types A and C. If we restrict to the coarse or univariate gradings, this obstruction is removed (Corollary 5.2); however, we have also seen that the two sides of (7.1) need not even have the same degree (Remark 4.3).

On the other hand, we claim that there is a large class of coherent parabolic subsystems. To describe this class, consider that the height functions in Φ and Φ_J are compatible, so Φ_J has an even-height root subsystem $\Phi_{J,0} \subseteq \Phi_0$, an even Weyl group $W(\Phi_{J,0}) = W_J \cap W(\Phi_0)$, and a W_J-normalizer $N(\Phi_{J,0}) = W(\Phi_{J,0}) \rtimes \Gamma(\Phi_{J,0})$. As noted previously, $\Gamma(\Phi_0)$ may be identified as the subgroup of $N(\Phi_0)$ consisting of elements with no even inversions, so there is an inclusion $N(\Phi_{J,0}) \subseteq N(\Phi_0)$ if and only if $\Gamma(\Phi_{J,0}) \subseteq \Gamma(\Phi_0)$. Moreover, one may test for this inclusion merely by checking that $y\alpha_j$ is odd for all $y \in \Gamma(\Phi_{J,0})$ and all $j \notin J$.

THEOREM 7.1. *If* $\Gamma(\Phi_{J,0}) \subseteq \Gamma(\Phi_0)$ *(or equivalently, $N(\Phi_{J,0}) \subseteq N(\Phi_0)$), then Φ_J is coherent. That is, we have $F_J(\Phi; \mathbf{q}) = F(\Phi; \mathbf{q})/F(\Phi_J; \mathbf{q})$ under the fine grading.*

We know that in many cases, $F(\Phi; \mathbf{q})/F(\Phi_J; \mathbf{q})$ is $G_J(\Phi; \mathbf{q})$, the sign-twisted series for the set ${}^J W_1$ of perfect coset representatives (Theorem 5.1). Thus one available strategy for proving coherence in some cases would be to show $F_J(\Phi; \mathbf{q}) = G_J(\Phi; \mathbf{q})$ directly.

LEMMA 7.2. *If* ${}^J W_1 \subset W(\Phi_0)$, *then* $F(\Phi; \mathbf{q})/F(\Phi_J; \mathbf{q}) = G_J(\Phi; \mathbf{q}) = F_J(\Phi; \bar{\mathbf{q}})$ *under the fine grading.*

Proof. It is clear that $F(\Phi_J; \mathbf{q}) = F(\Phi_J; y^{-1}\mathbf{q})$ for any $y \in {}^J W \cap W(\Phi_0)$, so the first equality is an immediate consequence of Theorem 5.1. For the second, note that

$$ {}^J W_1 \ \subseteq \ W(\Phi_0) \cap {}^J W \ \subseteq \ N(\Phi_0) \cap {}^J W. $$

On the other hand, any $y \in N(\Phi_0)$ has the property that $y^{-1}\alpha_i$ is odd for all i, and thus equality occurs throughout. We therefore have

$$ G_J(\Phi; \mathbf{q}) = \sum_{y \in N(\Phi_0) \cap {}^J W} \operatorname{sgn}(y) \prod_{\beta \in \Phi_1(y)} q_\beta = \sum_{y \in N(\Phi_0) \cap W^J} \operatorname{sgn}(y) \prod_{\beta \in \Phi_1(y^{-1})} q_\beta. $$

The only difference between the second sum and the expression for $F_J(\Phi; \mathbf{q})$ in Proposition 4.1 is the dependence on the inversion set for y^{-1} rather than y. However, the conditions for β to be an inversion for y (i.e., $\beta > 0$ and $y\beta < 0$) are also equivalent to having $-y\beta$ be an inversion for y^{-1}. Moreover, β is odd if and only if $-y\beta$ is odd, and the two roots necessarily belong to opposite $W(\Phi_0)$-orbits (since $y \in W(\Phi_0)$). Thus the above sum is identical to the result of substituting $\mathbf{q} \to \bar{\mathbf{q}}$ in Proposition 4.1. $\square$

Proof of Theorem 7.1. By definition, we have

$$ F(\Phi; \mathbf{q}) = \sum_{x \in W^J} \sum_{y \in W_J} \operatorname{sgn}(xy) \prod_{\beta \in \Phi_1(xy)} q_\beta. \tag{7.2} $$

By Proposition 4.1, this sum may be restricted to those pairs (x, y) with $xy \in N(\Phi_0)$.

Applying Lemma 4.2 to the pair $(\Phi_J, \Phi_\varnothing)$, we know that the map $y \mapsto s_j y$ (with j being the first fault of y relative to Φ_J) is a sign-reversing involution on the members of

W_J not in $N(\Phi_{J,0})$. Replacing y with $s_j y$ if necessary, we may assume $\ell(s_j y) > \ell(y)$. Since $\ell(xy) = \ell(x) + \ell(y)$ for all $x \in W^J$ and $y \in W_J$, Lemma 1.1 implies

$$\Phi(xy) = \Phi(y) \,\dot{\cup}\, y^{-1}\Phi(x),$$

$$\Phi(xs_j y) = \Phi(y) \,\dot{\cup}\, \{y^{-1}\alpha_j\} \,\dot{\cup}\, y^{-1}s_j\Phi(x)$$

$$= \Phi(y) \,\dot{\cup}\, \{y^{-1}\alpha_j\} \,\dot{\cup}\, ty^{-1}\Phi(x),$$

where $t = y^{-1}s_j y$ is the reflection corresponding to the root $y^{-1}\alpha_j \in \Phi_J$. However, j is the first fault of y relative to Φ_J, so this is an even root and t belongs to $W(\Phi_{J,0}) \subset W(\Phi_0)$. It follows that for each $W(\Phi_0)$-orbit of odd roots, the number of such roots is the same in $y^{-1}\Phi(x)$ and $ty^{-1}\Phi(x)$. Furthermore, $N(\Phi_0)$ includes $xs_j y = xyt$ if and only if it also includes xy. Thus the contributions of xy and $xs_j y$ to (7.2) cancel out under the fine grading, and we can require $y \in N(\Phi_{J,0})$ in addition to the restriction $xy \in N(\Phi_0)$.

Given the hypothesis that $N(\Phi_{J,0}) \subset N(\Phi_0)$, our restrictions on x and y can be separated into $x \in N(\Phi_0)$ and $y \in N(\Phi_{J,0})$. Since $\Phi_1(xy) = \Phi_1(y) \,\dot{\cup}\, y^{-1}\Phi_1(x)$, we obtain

$$F(\Phi; \mathbf{q}) = \sum_{x \in N(\Phi_0) \cap W^J} \sum_{y \in N(\Phi_{J,0})} \mathrm{sgn}(xy) \prod_{\beta \in \Phi_1(xy)} q_\beta$$

$$= \sum_{y \in N(\Phi_{J,0})} \left(\mathrm{sgn}(y) \prod_{\beta \in \Phi_1(y)} q_\beta \right) F_J(\Phi; y^{-1}\mathbf{q})$$

under the fine grading. It therefore suffices to show that

$$F_J(\Phi; \mathbf{q}) = F_J(\Phi; y^{-1}\mathbf{q}) \text{ for all } y \in N(\Phi_{J,0}). \tag{7.3}$$

Indeed, in that case we could factor $F_J(\Phi; \mathbf{q})$ out of the above sum, and Proposition 4.1 would clearly identify the remaining sum as $F(\Phi_J; \mathbf{q})$.

This invariance is immediate whenever y belongs to $W(\Phi_{J,0})$ (a subgroup of $W(\Phi_0)$), so we may assume $y \in \Gamma(\Phi_{J,0}) \subseteq \Gamma(\Phi_0)$ and that y acts nontrivially on the $W(\Phi_0)$-orbits of odd roots. We may also assume Φ_J is proper (otherwise W^J is trivial) and that $y \in \Gamma(\Phi_{K,0})$ for some irreducible component Φ_K of Φ_J, since $\Gamma(\Phi_{J,0})$ is generated by such groups. In that case, y may act non-trivially on the orbits of odd roots in at most one irreducible component of Φ (the one containing Φ_K), so we may further assume that Φ is irreducible. By Proposition 3.2, this is possible only if $\Phi \cong A_{2n-1}$ or C_n.

In these cases, there is only one nontrivial element $y \in \Gamma(\Phi_0)$, and Proposition 3.2 provides an explicit description of it. For A_{2n-1} and C_{2n-1}, it involves the simple reflections at both ends of the Dynkin diagram, and thus cannot belong to any proper parabolic subgroup of W that is irreducible. For C_{2n}, it is also the nontrivial element of $\Gamma(\Phi_{J,0})$, where Φ_J is the parabolic subsystem spanned by the short simple roots. Thus the conditions of the previous paragraph may be met only if $(\Phi, \Phi_J) \cong (C_{2n}, A_{2n-1})$. Since $\Gamma(\Phi_0)$ acts on the $W(\Phi_0)$-orbits by interchanging opposite pairs (Proposition 3.2 again), proving

$$F_J(\Phi; \mathbf{q}) = F_J(\Phi; \bar{\mathbf{q}}) \tag{7.4}$$

22

in this one case completes the proof of (7.3).

Our strategy for this case is to show that the conditions of Lemma 7.2 are met; i.e., that $W(\Phi_0)$ contains all of the perfect coset representatives. The key point is that the long roots of C_{2n} are all odd. Thus every $y \in {}^J W_1$ has the property that $y^{-1}\alpha_i$ is odd, whether α_i is short (i.e., $i \in J$) or α_i is long (i.e., $i \notin J$). In other words, ${}^J W_1 \subset N(\Phi_0)$, and the only question is whether ${}^J W_1$ (or the entirety of ${}^J W$) contains any elements in the nontrivial coset of $N(\Phi_0)/W(\Phi_0)$. For this, consider any $y \in {}^J W$. Using the coordinates for C_{2n} we introduced in Section 2, we claim that either $y\varepsilon_{2n} = \varepsilon_{2n}$ or $y\varepsilon_{2n} = -\varepsilon_1$. Otherwise, either $y\varepsilon_{2n} = \varepsilon_i$ for some $i < 2n$ or $y\varepsilon_{2n} = -\varepsilon_i$ for some $i > 1$. In the former case, we have $y^{-1}(\varepsilon_{i+1} - \varepsilon_i) = \pm\varepsilon_j - \varepsilon_{2n} < 0$ for some j, and in the latter case, we have $y^{-1}(\varepsilon_i - \varepsilon_{i-1}) = -\varepsilon_{2n} \pm \varepsilon_j < 0$ for some j. Either way, we contradict the fact that $y \in {}^J W$ and the claim follows. Thus y maps the (odd) root $2\varepsilon_{2n}$ to either $2\varepsilon_{2n}$ or $-2\varepsilon_1$. Both roots belong to the same $W(\Phi_0)$-orbit, so this confirms that every $y \in {}^J W_1$ belongs to $W(\Phi_0)$. Thus Lemma 7.2 implies

$$F_J(\Phi; \bar{\mathbf{q}}) = F(\Phi; \mathbf{q})/F(\Phi_J; \mathbf{q}) = F(C_{2n}; \mathbf{q})/F(A_{2n-1}; \mathbf{q})$$

under the fine grading. However, one can see from Theorem 6.1 that the right hand side is invariant under $\mathbf{q} \to \bar{\mathbf{q}}$, so the same is true for $F_J(\Phi; \mathbf{q})$ and (7.4) follows. □

REMARK 7.3. (a) The irreducible root systems for which $\Gamma(\Phi_0)$ is trivial are A_{2n}, E_6, E_8, F_4, and G_2 (see Table 1). Thus the conditions of Theorem 7.1 are easily met whenever the irreducible components of Φ_J are on this list. Conversely, if Φ is on this list, then this is the only way to meet the conditions.

(b) It follows in particular that the parabolic subsystems of A_{2n} whose irreducible components all have even rank are coherent. Conversely, it is easy to see from Theorem 6.1 that there are no other parabolic subsystems of A_{2n} with this property. Indeed, these are the only cases for which $F(\Phi_J; \mathbf{q})$ is a divisor of $F(\Phi; \mathbf{q})$.

(c) In the case $\Phi = B_n$, the nontrivial element in $\Gamma(\Phi_0)$ is the short simple reflection. Thus Theorem 7.1 in this case implies that a parabolic subsystem of B_n is coherent if each of its irreducible components contain either the short simple root or an even number of long simple roots.

(d) It seems likely that the converse of Theorem 7.1 is true; i.e., Φ_J is coherent if and only if $\Gamma(\Phi_{J,0}) \subseteq \Gamma(\Phi_0)$. We have confirmed this for all Φ of rank at most 8, and the argument in (b) confirms it for A_{2n}.

It appears that there is potential for a very general factorization theorem involving nearly all of the parabolic series $F_J(\Phi; \mathbf{q})$. For example, Brenti and Carnevale have proved explicit product formulas for all of the univariate parabolic series $F_J(A_n; q)$ and $F_J(B_n; q)$ (see Corollary 4.3 and Theorem 5.4 in [**BC1**]); the latter was also obtained independently by Landesman [**L**]. These formulas are clearly expressible as products of cyclotomic polynomials, so they support the following:

CONJECTURE 7.4. *If Φ is irreducible, then the univariate series $F_J(\Phi; q)$ is a product of cyclotomic polynomials unless*

(a) $\Phi \cong D_{2n}$ *and* $I \supsetneq J \supseteq K$, *where* $\Phi_K \cong A_1^{\oplus n+1}$, *or*
(b) $\Phi \cong E_7$ *and* $I \supsetneq J \supseteq K$, *where* $\Phi_K \cong A_1 \oplus D_4$, *or*
(c) $\Phi \cong E_8$ *and* $I \supsetneq J \supseteq K$, *where* $\Phi_K \cong D_6$.

Note that in each of (a)–(c), the subset $K \subset I$ is uniquely determined.

We have confirmed the above conjecture for all root systems of rank at most 8, so the only open cases involve C_n and D_n. Note that Brenti and Carnevale have explicit evaluations of the series $F_J(D_n; q)$ for the cases with $|J| = 1$, two cases with $|J| = 2$, and some conjectured evaluations in a few cases with $|J| \leqslant 3$ (see Sections 5–6 of [**BC3**]); all are consistent with the above conjecture.

REMARK 7.5. (a) One way to prove that $F_J(\Phi; q)$ factors into cyclotomic polynomials would be to show that it is a divisor of $F(\Phi; q)$. (And empirically, it does not seem to matter whether we use the fine, coarse, or univariate gradings—for ranks up through 8, all three gradings share the same divisibility properties.) We will not attempt to formulate a comprehensive conjecture, but it appears that (i) $F_J(\Phi; \mathbf{q})$ is always a divisor of $F(\Phi; \mathbf{q})$ under the fine grading for A_{2n} or B_n, and (ii) among the classical cases, a sufficient condition for divisibility is that $\Gamma(\Phi_0) \cap W_J$ is trivial. Unfortunately, this condition is not sufficient for the exceptional cases.

(b) An even stronger divisibility condition would be for

$$H_J(\Phi; \mathbf{q}) := \frac{F(\Phi; \mathbf{q})}{F_J(\Phi; \mathbf{q}) F(\Phi_J; \mathbf{q})}$$

to be a polynomial. If we assume Φ is irreducible and restrict to the coarse grading, so that $F(\Phi_J; \mathbf{q})$ is assured to be a divisor of $F(\Phi; \mathbf{q})$ (Corollary 5.2), the only examples we have found where $F_J(\Phi; \mathbf{q})$ divides $F(\Phi; \mathbf{q})$ but $H_J(\Phi; \mathbf{q})$ fails to be a polynomial involve D_n for $n \geqslant 7$ and violate the condition in (a); i.e., $\Gamma(\Phi_0) \cap W_J$ is nontrivial.

REMARK 7.6. It would be natural to investigate the analogue of $F_J(\Phi; \mathbf{q})$ in which the sum over W^J is replaced with a sum over $^J W$. However, these series do not appear to offer as much potential for factorization theorems. For example, when $\Phi = F_4$ or E_6, the univariate series factors into a product of cyclotomic polynomials only in the trivial case (i.e., $J = I$) and in the case $J = \varnothing$ (which coincides with the full series $F(\Phi; q)$). Out of the 64 choices for J available with $\Phi = C_6$ and 128 with D_7, only 6 in each case yield series that factor into cyclotomic polynomials.

8. A unified presentation of the univariate factorization

There is a uniform way to present the product formula for the univariate series $F(\Phi; q)$ that involves data attached to a root system canonically associated to Φ. To construct this second root system, we will need to work on the dual side with the co-root system $\Phi^\vee$.

Recall that the longest element w_0 of W induces a diagram automorphism of Φ and $\Phi^\vee$ via $\beta \mapsto -w_0\beta$. Let σ denote the induced map on the index set I for the simple roots and co-roots, and I/σ the set of σ-orbits on I. For each σ-orbit J, define

$$\alpha_J^\vee := \sum_{j \in J} \alpha_j^\vee = \begin{cases} \alpha_j^\vee & \text{if } j \in J \text{ and } \sigma(j) = j, \\ \alpha_j^\vee + \alpha_{\sigma(j)}^\vee & \text{if } j \in J \text{ and } \sigma(j) \neq j, \end{cases}$$

and let s_J denote the longest element of W_J. It is easy to check that either

(i) s_J is a simple reflection and $\alpha_J^\vee \in \Phi^\vee$ is simple, or

(ii) s_J is a product of two commuting simple reflections and $\alpha_J^\vee \notin \Phi^\vee$, or

(iii) s_J is the non-simple reflection in a copy of A_2 and $\alpha_J^\vee \in \Phi^\vee$ has height 2.

Note that (iii) occurs only if $\Phi^\vee$ has an irreducible component of type A with even rank. Indeed, this is the only circumstance in which σ reverses an edge of the Dynkin diagram.

Since conjugation by w_0 acts as a diagram automorphism of any σ-stable parabolic subgroup W_J, it follows that the longest element of any such W_J belongs to $Z(w_0)$, the centralizer of w_0. In particular, for each σ-orbit J, we have $s_J \in Z(w_0)$.

LEMMA 8.1. *The centralizer $Z(w_0)$ is generated by $\{s_J : J \in I/\sigma\}$.*

Proof. Consider that the $-w_0$-orbits $\{\beta^\vee, -w_0\beta^\vee\}$ in $\Phi^\vee$ are permuted by $Z(w_0)$ and that each orbit consists of all positive or all negative co-roots. It follows that if $w\alpha_j^\vee < 0$ for some $w \in Z(w_0)$, then the same is true for every index in the σ-orbit J of j, and thus w must be the longest element in its W_J-coset. Hence $\ell(ws_J) = \ell(w) - \ell(s_J)$ and it follows by induction that every member of $Z(w_0)$ has a length-additive expression as a product of elements chosen from $\{s_J : J \in I/\sigma\}$. $\square$

Let $V_{\pm 1}$ denote the ± 1-eigenspaces for the action of w_0 on the ambient space V that contains Φ and $\Phi^\vee$. Since w_0 is an involution, V is the direct sum of these eigenspaces. Moreover, it is easy to see that $\{\alpha_J^\vee : J \in I/\sigma\}$ is a basis for V_{-1}; the parameter

$$k := |I/\sigma| = \dim V_{-1}$$

will be important in what follows. Given that some of the generators s_J may be products of two commuting reflections as in (ii), it is clear that s_J need not be a reflection, and $Z(w_0)$ need not be a reflection subgroup of W. However as a centralizer, $Z(w_0)$ acts naturally on the eigenspaces of w_0, including V_{-1}.

LEMMA 8.2. *The centralizer $Z(w_0)$ acts faithfully on V_{-1}. Moreover, the generator s_J acts on V_{-1} as a reflection through the hyperplane orthogonal to $\alpha_J^\vee$.*

Proof. In case the σ-orbit J is of type (i) or (iii), s_J acts on V as a reflection through the hyperplane orthogonal to $\alpha_J^\vee$. Since $\alpha_J^\vee \in V_{-1}$, it restricts to a hyperplane reflection on V_{-1} as well. If J is of type (ii), so that s_J is a product of two commuting simple

reflections, say $s_i s_j$, then the -1-eigenspace of s_J on V is spanned by $\alpha_i^\vee$ and $\alpha_j^\vee$, but the intersection of this space with V_{-1} is spanned by $\alpha_J^\vee = \alpha_i^\vee + \alpha_j^\vee$, so again it acts as a hyperplane reflection on V_{-1}. If some $w \in Z(w_0)$ acts trivially on V_{-1}, it cannot have any inversions (as a member of W); otherwise, the proof of Lemma 8.1 shows that it would have to invert the simple co-roots $\alpha_j^\vee$ for all j in some σ-orbit J, and thus it would have to act nontrivially on $\alpha_J^\vee \in V_{-1}$. Hence the action is faithful. $\quad\square$

Define $\Phi^\vee/\sigma$ to be the set of $-w_0$-orbit sums in $\Phi^\vee$; i.e.,

$$\Phi^\vee/\sigma := \{\beta^\vee : w_0\beta^\vee = -\beta^\vee\} \cup \{\beta^\vee - w_0\beta^\vee : w_0\beta^\vee \neq -\beta^\vee\}. \qquad (8.1)$$

It is clear that $\Phi^\vee/\sigma$ is a union of $Z(w_0)$-orbits and that it contains each $\alpha_J^\vee$.

The following result is well-known; we include a proof for the sake of completeness.

PROPOSITION 8.3. *The orbit sums $\Phi^\vee/\sigma$ form a crystallographic root system in V_{-1} of (full) rank k with base $\{\alpha_J^\vee : J \in I/\sigma\}$. In particular, $Z(w_0)$ is isomorphic to the Weyl group $W(\Phi^\vee/\sigma)$ via a map in which s_J acts as the simple reflection corresponding to $\alpha_J^\vee$.*

Proof. Let $\Sigma = \{\alpha_J^\vee : J \in I/\sigma\}$. By Lemma 8.2, it suffices to confirm that

(a) every member of $\Phi^\vee/\sigma$ is in the nonnegative or nonpositive $\mathbb{Z}$-span of Σ,
(b) every $Z(w_0)$-orbit in $\Phi^\vee/\sigma$ meets Σ, and
(c) no nontrivial rescaling of $\Phi^\vee/\sigma$ intersects $\Phi^\vee/\sigma$ (i.e., $\Phi^\vee/\sigma$ is reduced).

Given a $-w_0$-orbit $\mathcal{O} = \{\beta^\vee, -w_0\beta^\vee\}$, we may exchange $\beta^\vee$ and $\mathcal{O}$ with $w_0\beta^\vee$ and $-\mathcal{O}$ if necessary so that $\beta^\vee > 0$. In that case, $\beta^\vee$ and $-w_0\beta^\vee$ must have nonnegative integer coordinates with respect to the simple roots of $\Phi^\vee$, so the same is true for the Σ-coordinates of the orbit sum, proving (a).

Since $w_0 \in Z(w_0)$ inverts all co-roots, there must be an element $w \in Z(w_0)$ and a generator s_J such that $w\mathcal{O}$ is a positive orbit and $s_J w\mathcal{O}$ is negative. However, s_J inverts only the roots in the subsystem $\Phi_J^\vee$; in most cases, this forces $w\mathcal{O}$ to be $\{\alpha_j^\vee : j \in J\}$ and the corresponding orbit sum to be $\alpha_J^\vee$. The one exception occurs when the σ-orbit J is of type (iii), in which cases there are two positive $-w_0$-orbits in $\Phi_J^\vee$: one singleton and one doubleton. However they both have sum $\alpha_J^\vee$, so (b) follows either way. (This also shows that the union in (8.1) need not be disjoint.)

Finally, suppose $\Phi^\vee/\sigma$ and $k\Phi^\vee/\sigma$ had a nontrivial intersection for some scalar $k > 1$. In that case, (b) would force some $Z(w_0)$-orbit in $\Phi^\vee/\sigma$ to have Σ-coordinates in $k\mathbb{Z}$, contradicting the fact that the orbit must include some $\alpha_J^\vee$. $\quad\square$

Now let $L_0^\vee$ denote the kernel of the parity morphism $\mathbb{Z}\Phi^\vee \to \mathbb{Z}/2\mathbb{Z}$ in which every simple co-root is odd; this is the co-root counterpart to the lattice L_0 we introduced in Section 1. Having constructed a root system $\Phi^\vee/\sigma$ contained in $\mathbb{Z}\Phi^\vee$, it follows that

$$(\Phi^\vee/\sigma)_0 := L_0^\vee \cap (\Phi^\vee/\sigma)$$

Φ	Φ_0	$\Phi^\vee/\sigma$	$(\Phi^\vee/\sigma)_0$	k
A_{2n-1}	$A_{n-1}\oplus A_{n-1}$	B_n	D_n	n
A_{2n}	$A_n\oplus A_{n-1}$	B_n	B_n	n
B_{2n}	$B_n\oplus D_n$	C_{2n}	A_{2n-1}	$2n$
B_{2n+1}	$B_n\oplus D_{n+1}$	C_{2n+1}	A_{2n}	$2n+1$
C_{2n}	A_{2n-1}	B_{2n}	$B_n\oplus D_n$	$2n$
C_{2n+1}	A_{2n}	B_{2n+1}	$B_n\oplus D_{n+1}$	$2n+1$
D_{2n}	$D_n\oplus D_n$	D_{2n}	$D_n\oplus D_n$	$2n$
D_{2n+1}	$D_n\oplus D_{n+1}$	C_{2n}	$C_n\oplus C_n$	$2n$
E_6	$A_5\oplus A_1$	F_4	B_4	4
E_7	A_7	E_7	A_7	7
E_8	D_8	E_8	D_8	8
F_4	$C_3\oplus A_1$	F_4	$C_3\oplus A_1$	4
G_2	$A_1\oplus A_1$	G_2	$A_1\oplus A_1$	2

TABLE 3: A listing of Φ_0, $\Phi^\vee/\sigma$, $(\Phi^\vee/\sigma)_0$, and $k = \dim V_{-1}$ for irreducible Φ.

is a root subsystem of $\Phi^\vee/\sigma$. Note that if w_0 acts as -1 on $\Phi^\vee$, the involution σ is trivial, $\Phi^\vee/\sigma = \Phi^\vee$, and $(\Phi^\vee/\sigma)_0 = L_0^\vee \cap \Phi^\vee$ is simply the even-height root subsystem of $\Phi^\vee$.

It is important to note that in general, some of the simple roots of $\Phi^\vee/\sigma$ may be "even" (i.e., members of $L_0^\vee$) and thus part of $(\Phi^\vee/\sigma)_0$. That is, the parity that $L_0^\vee$ induces on $\Phi^\vee/\sigma$ need not be the one that declares all of its simple roots to be odd.

EXAMPLE 8.4. Consider $\Phi = A_n$, with the diagram numbered $1-2-\cdots-n$. Here, the action of σ is such that $\sigma(i) = n+1-i$. If $n = 2r$, the simple roots of $\Phi^\vee/\sigma$ are

$$\alpha_r^\vee + \alpha_{r+1}^\vee, \quad \alpha_{r-1}^\vee + \alpha_{r+2}^\vee, \ldots, \quad \alpha_1^\vee + \alpha_{2r}^\vee.$$

The first one is of type (iii) while the others are of type (ii) and thus longer, and it is not hard to check that the root system they generate is isomorphic to B_r. Moreover, all of these roots are in $L_0^\vee$, so we have $\Phi^\vee/\sigma = (\Phi^\vee/\sigma)_0 \cong B_r$. On the other hand, if $n = 2r-1$, the simple roots of $\Phi^\vee/\sigma$ are

$$\alpha_r^\vee, \quad \alpha_{r-1}^\vee + \alpha_{r+1}^\vee, \ldots, \quad \alpha_1^\vee + \alpha_{2r-1}^\vee.$$

The first one is again short, but it is of type (i) and has odd height in $\Phi^\vee$. Thus $\Phi^\vee/\sigma \cong B_r$, but in this case $(\Phi^\vee/\sigma)_0 \cong D_r$ contains only the long roots. (In the somewhat degenerate case $\Phi = A_1$, one should recognize that $(\Phi^\vee/\sigma)_0 \cong D_1$ is an empty root system.)

In Table 3, we list the isomorphism classes of Φ_0, $\Phi^\vee/\sigma$, and $(\Phi^\vee/\sigma)_0$ as well as the parameter $k = \dim V_{-1}$ (the rank of $\Phi^\vee/\sigma$) for each irreducible Φ.

To place the following result in its proper context, recall that for any finite reflection group action, such as W acting on V, there is a canonically associated multiset of positive integers $d_1, \ldots, d_m$ (where $m = \dim V$). These are the degrees of a homogeneous set of free generators for the W-invariants in the symmetric algebra $S(V)$. (The existence of such generators is a well-known theorem of Chevalley; e.g., see [**H**, §3.5].)

THEOREM 8.5. *If $a_1, \ldots, a_k$ are the degrees of the free generating invariants for the action of $W((\Phi^\vee/\sigma)_0)$ on $S(V_{-1})$, then*

$$F(\Phi; q) \;=\; \prod_{i=1}^{k}(1 - q^{a_i}).$$

Proof. It suffices to prove this when Φ is irreducible. In such cases, we may obtain the univariate series $F(\Phi; q)$ by specializing Theorem 6.1. On the product side, one may use Table 3 to determine the degrees $a_1, \ldots, a_k$. Since the components of $(\Phi^\vee/\sigma)_0$ are always of classical type, one only needs to know that the degrees of the generating invariants for the action on the span of such a component are as follows:

$$A_n : \; 2, 3, \ldots, n+1,$$
$$B_n, C_n : \; 2, 4, 6, \ldots, 2n,$$
$$D_n : \; n, 2, 4, 6, \ldots, 2n-2.$$

It should be noted that the rank r of $(\Phi^\vee/\sigma)_0$ may be less than k, in which case the action of $W((\Phi^\vee/\sigma)_0)$ on the span of $(\Phi^\vee/\sigma)_0$ accounts for only r of the k generating invariants in $S(V_{-1})$. In such cases, the remaining $k - r$ generators all have degree 1. (This happens when $\Phi \cong A_1$, C_2, or B_n.) $\square$

REMARK 8.6. (a) Let $G = W((\Phi^\vee/\sigma)_0)$. The Hilbert series for the G-invariants is

$$H(S(V_{-1})^G; q) = \prod_{i=1}^{k} \frac{1}{1 - q^{a_i}},$$

so an equivalent formulation of Theorem 8.5 is the identity

$$F(\Phi; q)\, H(S(V_{-1})^G; q) = 1.$$

(b) The degrees of the generating invariants also appear in Chevalley's formula for the (untwisted) Poincaré series $P(W; q) = \sum_{w \in W} q^{\ell(w)}$ for any Weyl group W (e.g., see [**H**, §3.15]). Thus another way to formulate Theorem 8.5 is the identity

$$\frac{F(\Phi; q)}{(1 - q)^k} \;=\; P(W((\Phi^\vee/\sigma)_0); q). \tag{8.2}$$

It should be stressed that the length function here is the one intrinsic to the Weyl group of the root system $(\Phi^\vee/\sigma)_0$. It is not the same as the length functions for the Weyl groups of $\Phi^\vee/\sigma$ or Φ (although the proof of Lemma 8.1 shows that the latter two are related). Note also that the factor $(1-q)^{-k}$ and the right hand side of (8.2) may be interpreted as the Hilbert series for $S(V_{-1})$ and its associated co-invariant algebra, respectively.

(c) It would be interesting to develop a multivariate refinement of Theorem 8.5 for either the coarse or fine gradings of $F(\Phi; \mathbf{q})$. In this context it should be noted that Macdonald has given a coarse refinement of $P(W; q)$ for any Weyl group W [**M**].
